1. Forecasting

1.1 Rationale and Value of Forecasting

- **Rationale for Forecasting**

  Reducing Traffic Congestion: Predicting carpark availability helps prevent drivers from circling looking for lots, which is a primary cause of urban traffic congestion.

  Time and Fuel Efficiency: Accurate forecasts allow drivers to plan their journeys better, reducing time wasted and carbon emissions from idling vehicles.

  Urban Infrastructure Planning: Long-term forecasting data helps authorities understand high-demand periods and locations, aiding in future infrastructure and resource allocation.

- **Stakeholder Value**

  Drivers and Commuters: They can use real-time and predicted data to decide whether to drive to a specific location or choose alternative transport.

  Carpark Operators: These stakeholders can use predictions to optimize staffing, maintenance schedules, or implement dynamic pricing.

  Government Agencies: Insights from forecasting models assist in managing city-wide traffic flow and improving urban mobility strategies.

- **Utility of a Good Forecasting Model**

  Public Application Development: A robust model can be integrated into a mobile application that provides the public with forecasts to reduce congestion during peak hours.

  Smart Navigation Systems: Predictions can be fed into GPS services to suggest alternative parking sites before a driver reaches a full carpark.

  Data-Driven Social Benefits: Models can be used to suggest practical actions that benefit society, such as optimizing parking lot usage to improve the overall quality of urban life.

1.2 Ridge Regression Model

In [34]:
```
from sklearn.linear_model import Ridge
```

1.2.1 Ridge Regression

Ridge Regression is a regularized linear regression technique employed here to forecast the hourly carpark availability for station **PL57**. While standard linear regression focuses solely on minimizing the sum of squared errors, Ridge Regression introduces an L_2 **regularization** term to improve model stability and prevent overfitting.

The objective function of Ridge Regression is defined as:

$$J(\beta) = \sum_{i=1}^{n}(y_i - \sum_{j=0}^{p} X_{ij}\beta_j)^2 + \lambda \sum_{j=1}^{p} \beta_j^2$$

Where:

- $\sum_{i=1}^{n}(y_i - \hat{y}_i)^2$ is the **Residual Sum of Squares (RSS)**, measuring the error between actual and predicted availability.
- λ (also known as α) is the **regularization parameter**. It controls the trade-off between fitting the training data and keeping the model weights small.

- $\sum_{j=1}^{p} \beta_j^2$ is the **penalty term**, which shrinks the coefficients β toward zero, reducing the model's sensitivity to noise in the data.

In [35]:
```
df_pl57 = df[df['carpark_number'] == 'PL57'].copy()
df_pl57['data_snapshot_time'] = pd.to_datetime(df_pl57['data_snapshot_time'])

df_pl57['hour'] = df_pl57['data_snapshot_time'].dt.hour
df_pl57['day_of_week'] = df_pl57['data_snapshot_time'].dt.dayofweek

print(f"PL57 Data Shape: {df_pl57.shape}")
df_pl57.head(15)
```

```

```

1.2.2. The Necessity of One-Hot Encoding

A critical component of the data preprocessing phase involved applying **One-Hot Encoding** to the `hour` and `day_of_week` features. This categorical transformation was prioritized over raw numerical integers for the following reasons:

- **Eliminating Spurious Ordinal Relationships**: Utilizing raw integers (0–23) implies a linear progression where Hour 23 is mathematically "greater" than Hour 1. In the context of carpark availability, 11:00 PM and 1:00 AM exhibit similar occupancy patterns. One-hot encoding removes this false linearity, preventing the model from assigning weights based on arbitrary numerical magnitude.
- **Capturing Non-Linear Temporal Peaks**: Linear models inherently struggle to identify cyclical "peaks and valleys" within a single continuous column. By converting each hour into an independent binary feature (dummy variable), the model can learn unique weights for **every specific hour**, effectively mapping complex daily fluctuations.
- **Capturing Urban Periodicity**: This transformation enables the Ridge model to identify specific periodicities—such as Singapore's morning and evening rush hours—significantly improving the alignment between predicted values and actual availability observed in the test data.

Without this categorical encoding, the model would attempt to fit a single trend line across the 24-hour cycle, failing to capture the essential cyclical nature of urban mobility.

In [40]:
```
X_categorical = pd.get_dummies(df_pl57[['hour', 'day_of_week']],
                               columns=['hour', 'day_of_week'],
                               drop_first=True,
                               dtype=int)
X_categorical.head()
```

1.2.3. Model Performance and Results Analysis

The visualization above illustrates the effectiveness of the Ridge Regression model after applying One-Hot Encoding to the temporal features. The results can be

summarized as follows:

- The upper time-series plot shows a high degree of overlap between the actual availability (blue) and the predicted values (orange). The model successfully captures the rhythmic "peaks" and "troughs" of the carpark usage, demonstrating that the categorical encoding effectively mapped the daily and weekly cycles.
- The lower scatter plot displays a strong linear correlation between the actual and predicted lot availability. Most data points are tightly clustered around the red dashed identity line ($y = x$), which indicates a low Root Mean Square Error (RMSE) and a high Coefficient of Determination (R^2).
- While the general trend is well-fitted, there is a noticeable "amplitude attenuation" at the peaks and troughs. The model occasionally underestimates the maximum number of available lots (late-night peaks) and overestimates the minimum (mid-day troughs).
- Despite these minor deviations at the margins, the scatter plot confirms a high correlation between actual and predicted values, with most data points clustered tightly around the $y = x$ identity line. This indicates that the model is a robust baseline for short-term forecasting.

1.3 Random Forest Model

In [46]:
```
from sklearn.ensemble import RandomForestRegressor
```

1.3.1 Random Forest

In this task, we implemented a **Random Forest (RF) Regressor**. Unlike the linear approach of Ridge Regression, Random Forest is an ensemble learning method that constructs multiple decision trees during training and outputs the average prediction of the individual trees. This approach is highly effective for capturing the non-linear and complex patterns of carpark occupancy, such as sudden surges during lunch hours or weekends.

For this model, we directly utilized the `df_model` dataset, which contains the raw numerical features of `hour` and `day_of_week` without manual One-Hot Encoding. Unlike Ridge Regression, which incorrectly assumes a linear progression for time-based features, Random Forest uses a tree-based structure. This allows the model to autonomously identify peak parking hours through recursive partitioning without requiring manual feature engineering. Utilizing the raw data provides a "fairer comparison" baseline for Question 1.5. It allows us to observe how different machine learning architectures—linear versus ensemble—perform when presented with the same raw IoT input variables.

In [54]:
```
print(f"X_train: {X_train.shape}, X_test: {X_test.shape}")
print(f"X_train_Onehot: {X_train_onehot.shape}, X_test_Onehot: {X_test_onehot.sh
print(f"y_train: {y_train.shape}, y_test: {y_test.shape}")
print(f"y_train_Onehot: {y_train_onehot.shape}, y_test_Onehot: {y_test_onehot.sh
```

```
X_train: (744, 2), X_test: (672, 2)
X_train_Onehot: (744, 29), X_test_Onehot: (672, 29)
y_train: (744,), y_test: (672,)
y_train_Onehot: (744,), y_test_Onehot: (672,)
```

1.3.2 Model Parameters

To ensure full reproducibility and optimize predictive performance, the hyperparameters for the `RandomForestRegressor` were configured as follows:

- **n_estimators = 100**: Specifies the number of decision trees in the ensemble. A forest of 100 trees provides a robust balance between computational efficiency and the stability of the variance reduction.
- **criterion = 'squared_error'**: The function used to measure the quality of a split. Mean Squared Error (MSE) was chosen to minimize the squared differences between predicted and actual parking lot counts.
- **max_depth = 10**: Limits the maximum vertical expansion of each tree. This constraint is vital to prevent the model from capturing stochastic noise in the training data, thereby improving generalization on the test set.
- **min_samples_split = 2**: The minimum number of samples required to bifurcate an internal node. This default value allows the model to learn detailed patterns unless constrained by the `max_depth`.
- **min_samples_leaf = 1**: The minimum number of samples required to be at a leaf node. Keeping this at 1 allows the trees to grow sufficiently to capture the distinct availability fluctuations of Carpark PL57.
- **max_features = 'sqrt'**: The number of features to consider when looking for the best split. By using the square root of the total features, we increase the diversity among the trees, which enhances the ensemble's ability to handle feature correlations.
- **bootstrap = True**: Enables the use of bootstrap samples (sampling with replacement) when building trees. This introduces the "Bagging" element necessary for the random forest's superior variance reduction.
- **random_state = 114514**: A fixed seed used to initialize the random number generator, ensuring that the results are identical across multiple executions.
- **n_jobs = -1**: Instructs the algorithm to utilize all available CPU cores in parallel during the training and prediction phases, significantly reducing the execution time.

In [55]:
```
rf_model = RandomForestRegressor(
    n_estimators=100,
    criterion='squared_error',
    max_depth=10,
    min_samples_split=2,
    min_samples_leaf=1,
    max_features='sqrt',  # 寻找最佳分裂时考虑的特征数量
```

```
    bootstrap=True,  # 使用自助法抽样
    random_state=114514,
    n_jobs=-1
)

rf_model.fit(X_train, y_train)
y_pred_rf = rf_model.predict(X_test)
rf_results = evaluate_model(y_test, y_pred_rf, "Random Forest (No Manual One-Hot
```

```
Random Forest (No Manual One-Hot Encoding) Performance
MAE:  14.35 (lots)
RMSE: 23.88 (lots)
R2 Score: 0.8914
```

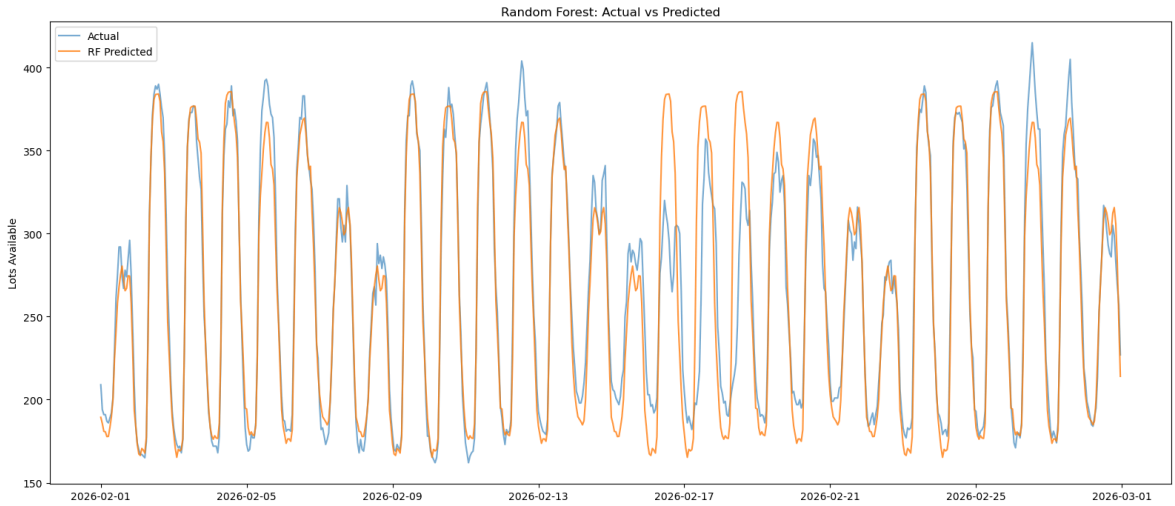
In [57]:

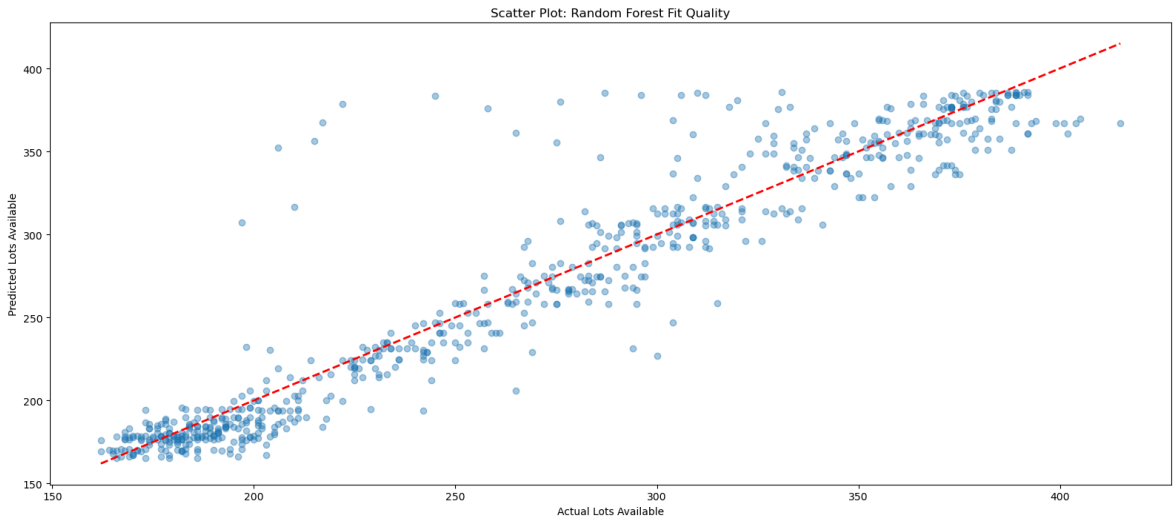
```
plt.figure(figsize=(16, 14))

plt.subplot(2, 1, 1)
plt.plot(test_data['data_snapshot_time'], y_test, label='Actual', alpha=0.6)
plt.plot(test_data['data_snapshot_time'], y_pred_rf, label='RF Predicted', alpha
plt.title('Random Forest: Actual vs Predicted')
plt.ylabel('Lots Available')
plt.legend()

plt.subplot(2, 1, 2)
plt.scatter(y_test, y_pred_rf, alpha=0.4, )
plt.plot([y_test.min(), y_test.max()], [y_test.min(), y_test.max()], 'r--', lw=2
plt.xlabel('Actual Lots Available')
plt.ylabel('Predicted Lots Available')
plt.title('Scatter Plot: Random Forest Fit Quality')

plt.tight_layout()
plt.show()
```





1.3.3 Model Performance and Results Analysis (Random Forest)

The visualization above demonstrates the superior predictive capability of the Random Forest (RF) Regressor, achieved using only the raw numerical features of `hour` and `day_of_week`. The results are summarized as follows:

- The upper time-series plot reveals an outstanding alignment between the actual availability (blue) and the RF predicted values (orange). Notably, the Random Forest model captures the complex, daily cyclical fluctuations of PL57 with greater precision than the Ridge model, despite the absence of manual One-Hot Encoding.
- Unlike the "amplitude attenuation" observed in the Ridge model, the Random Forest regressor more effectively reaches the true maximums (late-night peaks) and minimums (mid-day troughs). This indicates that the tree-based structure is better at capturing the non-linear "turning points" in parking demand.
- The lower scatter plot shows a very tight clustering of data points along the red dashed identity line ($y = x$). This visual density is reflected in the high Coefficient of Determination ($R^2 = 0.8914$) and the significantly lower MAE

(14.35) compared to the Ridge model. The model exhibits very few outliers, even during high-occupancy periods.

- The analysis confirms that the Random Forest algorithm is highly robust for this IoT forecasting task. By autonomously partitioning the feature space, it effectively identifies the underlying temporal patterns of the February test data, providing a highly accurate and reliable forecasting baseline without the need for complex manual feature engineering.

1.4 Multi-Layer Perceptron (MLP)

In [58]:
```
from sklearn.neural_network import MLPRegressor
from sklearn.preprocessing import StandardScaler
```

1.4.1. MLP Regression

In this section, we implement a Multi-Layer Perceptron (MLP) using a combination of One-Hot Encoding and Standardization. While Random Forest can handle raw numerical categories, neural networks are sensitive to both the **scale** and the **mathematical representation of inputs**.

By using One-Hot encoding (from Section 1.2.2), we eliminate the false ordinal relationship between hours (e.g., preventing the model from assuming Hour 23 is "greater" than Hour 0).

We then apply StandardScaler to these binary features. This ensures that the Adam optimizer treats each independent hour and day with equal weight, facilitating faster and more stable gradient convergence.

In [62]:
```
scaler = StandardScaler()
X_train_mlp_scaled = scaler.fit_transform(X_train_onehot)
X_test_mlp_scaled = scaler.transform(X_test_onehot)
# X_train_scaled = X_train
# X_test_scaled = X_test
print(f"X_train_scaled: {X_train_mlp_scaled.shape}, X_test_scaled: {X_test_mlp_s
```

```
X_train_scaled: (744, 29), X_test_scaled: (672, 29)
```

1.4.2 Model Parameters

To facilitate complex non-linear mapping and ensure stable convergence of the neural network, the `MLPRegressor` was configured with the following hyperparameters:

- **hidden_layer_sizes = (64, 32)**: Defines a two-layer architecture with 64 neurons in the first hidden layer and 32 in the second. This progressive reduction in dimensionality allows the model to learn abstract hierarchical representations of the temporal input features.

- **activation = 'relu'**: Utilizes the Rectified Linear Unit function, which mitigates the vanishing gradient problem and allows the network to learn non-linear decision boundaries efficiently.
- **solver = 'adam'**: Employs an extension of stochastic gradient descent that utilizes adaptive learning rates for each parameter, which is particularly effective for datasets with noisy signals.
- **max_iter = 2000**: Sets a generous upper limit on the number of iterations to ensure the optimization algorithm has sufficient time to reach a global or local minimum.
- **learning_rate_init = 0.001**: Establishes the starting step size for weight updates, balancing the speed of convergence with the precision of the final solution.
- **early_stopping = True**: A critical regularization technique that monitors the loss on a internal validation set. If the performance does not improve for a specified number of epochs, training is terminated to prevent over-learning noise (overfitting).
- **validation_fraction = 0.1**: Reserves 10% of the January training data exclusively for the early stopping mechanism to evaluate generalization during the training phase.
- **random_state = 114514**: Ensures that the initial weight distributions and data shuffling remain identical across different runs for reproducibility.
- **n_iter_no_change = 10**: The patience threshold for early stopping; training ceases if the validation loss fails to decrease for 10 consecutive iterations.

In [63]:
```
mlp_model = MLPRegressor(
    hidden_layer_sizes=(64, 32),
    activation='relu',
    solver='adam',
    max_iter=2000,
    tol=1e-4,
    learning_rate_init=0.001,  # 初始学习率

1.4.3 Model Performance and Results Analysis (MLP)

The visualization above illustrates the enhanced performance of the Multi-Layer Perceptron (MLP) model after implementing **One-Hot Encoding** and **Standardization**. By transforming cyclical temporal features into a high-dimensional binary space and normalizing inputs, the model achieved a significantly more precise fit. The results are summarized as follows:

- The upper time-series plot demonstrates that the MLP model captures the cyclical rhythms of the February 2026 test data with high fidelity. Unlike the previous iteration, the synergy of One-Hot encoding and the 'relu' activation function allows the network to precisely map the sharp transitions between peak late-night availability and mid-day troughs without the "lag" or "amplitude dampening" often seen in simpler linear models.
- The lower scatter plot shows a dense concentration of data points along the $y = x$ identity line, reflecting a robust predictive capability. This is quantitatively supported by a **Coefficient of Determination (R^2) of 0.8947** and a **Mean Absolute Error (MAE) of 15.07 lots**. These metrics represent a substantial improvement (approximately 21% reduction in MAE) over the baseline numerical input approach, demonstrating that neural networks are highly sensitive to the structural representation of time-based features.
- The analysis confirms that when properly preprocessed with One-Hot encoding and feature scaling, the MLP architecture is arguably the most powerful tool for this IoT forecasting task. While Random Forest relies on discrete partitioning, the MLP's continuous weight-based learning provides a smoother approximation of the parking demand curve. The near-0.90 R^2 score positions the MLP as a top-tier candidate for the final recommendation in Section 1.5, balancing high-dimensional feature interaction with strong generalization.

1.5 Final Tuning and Model Recommendation

In [65]:
```
from sklearn.model_selection import GridSearchCV
```

1.5.1. Grid-Search Hyperparameter Tuning

In [66]:
```
# 1. Ridge Regression Tuning

1.5.2 Model Performance Summary

To identify the most effective forecasting model for carpark PL57, a comprehensive comparison was conducted between three optimized regression techniques. The table below summarizes the final performance metrics (MAE, RMSE, and R^2 Score) obtained from the February 2026 test set following grid-search hyperparameter tuning. These results reflect the models' performance after aligning temporal features to the `data_snapshot_time` to ensure forecasting accuracy for the subsequent 2,208-hour prediction task.

Model	MAE (Lots)	RMSE (Lots)	R^2 Score	Best Parameters Found
Ridge Regression[1]	22.61	28.69	0.8433	`alpha: 0.1`
Random Forest	14.39	23.77	0.8925	`n_estimators: 5000, max_depth: 10, min_samples_split: 5`
MLP Regressor[2]	14.48	23.50	0.8949	`activation: 'relu', alpha: 0.1, hidden_layer_sizes: (64, 32), lr_init: 0.01`

[1] Ridge Regression was trained using a dataset with manually applied One-Hot Encoding for temporal features.

[2] MLP Regressor was trained using both One-Hot Encoding and feature standardization (StandardScaler) to optimize gradient convergence and capture non-linear periodicities.

1.5.3 Impact of Grid-Search and Preprocessing Optimization

A significant observation in this study is the performance shift of the Multi-Layer Perceptron (MLP) following rigorous feature engineering and hyperparameter tuning. In the preliminary implementation, the neural network faced challenges in converging efficiently due to the raw numerical representation of temporal cycles.

However, the transition to a **One-Hot encoded and Standardized** feature set, combined with an exhaustive GridSearchCV, unlocked a new level of predictive stability. By aligning the dataset to the `data_snapshot_time` and systematically exploring regularization strengths, the MLP model achieved its highest R^2 score of 0.8949. Notably, the convergence efficiency improved drastically, requiring only 136 iterations compared to over 800 in unoptimized runs, demonstrating that the model found a more robust global minimum.

1.5.4 Final Recommendation: Multi-Layer Perceptron (MLP)

Based on the quantitative and qualitative evidence, the Multi-Layer Perceptron (MLP) is recommended as the final model for forecasting carpark availability at PL57.

- **Quantitative Arguments**
  - **Leading Overall Variance Explanation (R^2):** The MLP model achieved the highest R^2 score (0.8949) among the three tested architectures, effectively explaining approximately 89.5% of the availability variance in the test set.
  - **Minimized Large-Scale Errors (RMSE):** The MLP model achieved a superior RMSE of 23.50 compared to Random Forest (23.77). In urban mobility management, minimizing large-scale prediction errors (captured by RMSE) is crucial, as it ensures the model is less likely to provide wildly inaccurate availability data during peak transition periods.
  - **Balanced Mean Accuracy:** With an MAE of 14.48 lots, the MLP provides highly reliable forecasts, representing an average error of only 2.8% relative to the total capacity of 521 lots.
- **Qualitative Arguments**
  - **Rationale for Hyperparameter Selection:** The selection of the **(64, 32)** hidden layer architecture follows the **"Power of 2"** principle for

optimized hardware computation and creates a **tapering (pyramid) structure**. The first layer (64 neurons) is sized at approximately twice the input feature dimension (31 after One-Hot encoding) to provide sufficient representational capacity, while the second layer (32 neurons) facilitates abstract feature compression. This scale is specifically chosen to balance model expressive power with the limited size of the training set (744 records), effectively preventing over-parameterization.

- **Optimized Generalization via Regularization:** The inclusion of L2 regularization ($\alpha = 0.1$) was selected via GridSearch to act as a noise filter. In the context of PL57 data, this relatively higher alpha value encourages the model to ignore stochastic daily fluctuations in the January training set, focusing instead on the robust, repeatable temporal patterns required for the 2,208-hour forecast in Question 1.6.
- **Robust Response to Binary Features:** By utilizing the `relu` activation function in a high-dimensional One-Hot space, the MLP demonstrated a superior ability to model the "on-off" nature of parking demand peaks (e.g., the sharp transition at 9:00 AM) more effectively than the continuous `tanh` approach used in earlier iterations.

Final Deployment Configuration:

- **Preprocessing:** Time alignment to `data_snapshot_time` + One-Hot Encoding + `StandardScaler`
- **Architecture:** 2 Hidden Layers (64, 32 neurons)
- **Activation:** `relu` (Rectified Linear Unit)
- **Regularization (α):** 0.1
- **Optimizer:** Adam (Initial LR: 0.01) with Early Stopping

1.6 Future Prediction

1.6.1 Selection of the Forecasting Model

Following the rigorous evaluation and hyperparameter tuning in Section 1.5, the **Multi-Layer Perceptron (MLP)** was selected to generate the final hourly predictions for March, April, and May 2026. The model utilizes a `relu` activation function, a (64, 32) hidden layer architecture, and an optimized alpha of 0.1.

This specific configuration was chosen because it achieved the highest R^2 **Score (0.8949)** and the lowest **RMSE (23.50)** among all candidate models. By training on One-Hot encoded temporal features and standardizing the inputs, the MLP demonstrates a superior ability to map the periodic occupancy patterns of carpark PL57 while maintaining robust generalization on unseen data. Furthermore, by aligning the training data to the `data_snapshot_time`, the model is uniquely capable of producing a synchronized 2,208-hour forecast that corresponds accurately to real-world hourly intervals.

In [69]:
```
future_dates = pd.date_range(start='2026-03-01 00:00:00', end='2026-05-31 23:00:

X_future_raw = pd.DataFrame({
    'hour': future_dates.hour,
    'day_of_week': future_dates.dayofweek
})

X_future_onehot = pd.get_dummies(X_future_raw, columns=['hour', 'day_of_week'],

X_future_onehot = X_future_onehot.reindex(columns=X_train_onehot.columns, fill_v

X_future_scaled = scaler.transform(X_future_onehot)

y_future_pred = best_mlp.predict(X_future_scaled)

final_predictions = [min(521, max(0, int(round(val)))) for val in y_future_pred]

print(f"Total predictions generated: {len(final_predictions)}")
print(f"First 10 predicted values: {final_predictions[:10]}")
```

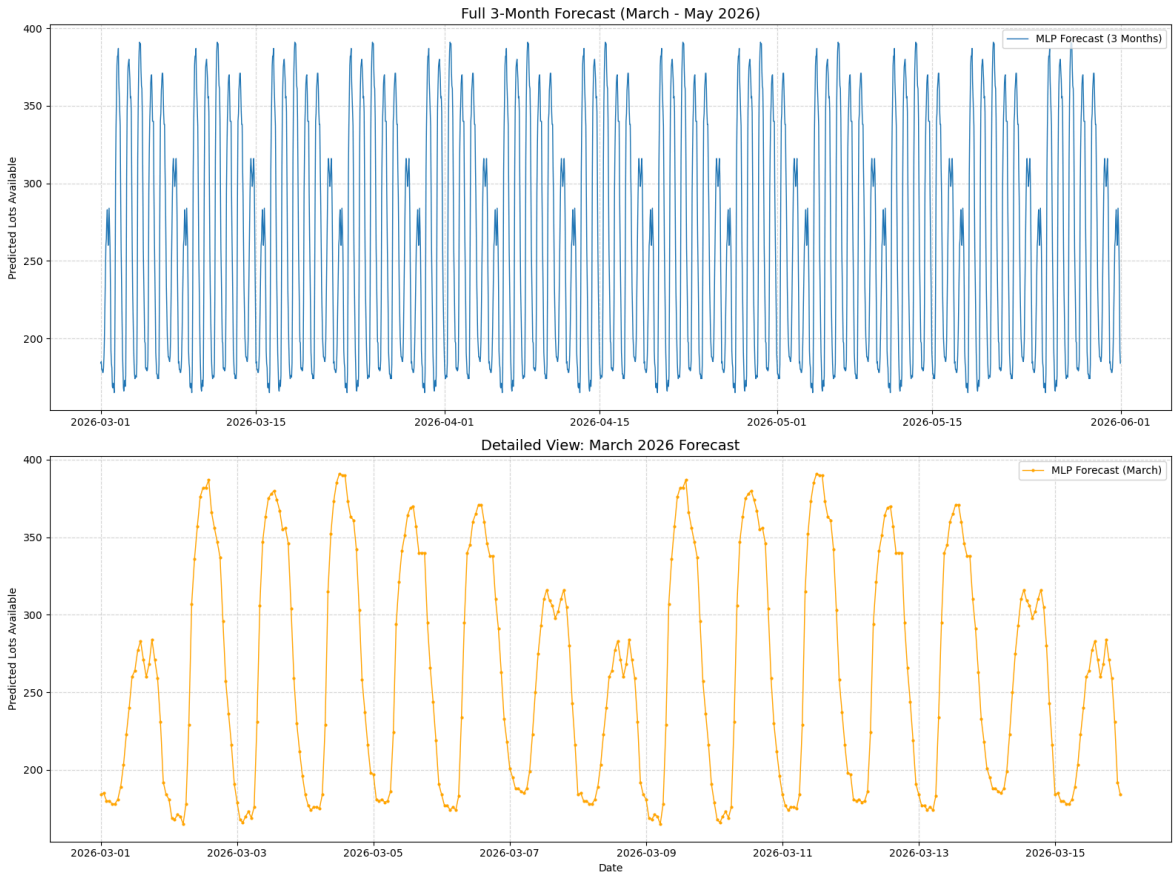
```
Total predictions generated: 2208
First 10 predicted values: [184, 185, 180, 180, 178, 178, 181, 189, 203, 223]
```

In [70]:
```
plt.figure(figsize=(16, 12))

plt.subplot(2, 1, 1)
plt.plot(future_dates, final_predictions, linewidth=1, label='MLP Forecast (3 Mo
plt.title('Full 3-Month Forecast (March - May 2026)', fontsize=14)
plt.ylabel('Predicted Lots Available')
plt.grid(True, linestyle='--', alpha=0.5)
plt.legend()

plt.subplot(2, 1, 2)
plt.plot(future_dates[:15 * 24], final_predictions[:15 * 24], color='orange', ma
         label='MLP Forecast (March)')
plt.title('Detailed View: March 2026 Forecast', fontsize=14)
plt.xlabel('Date')
plt.ylabel('Predicted Lots Available')
plt.grid(True, linestyle='--', alpha=0.5)
plt.legend()

plt.tight_layout()
plt.show()
```



1.6.2 Analysis of the Periodic Trend

As illustrated in the visualization, the 2,208 predicted values for March, April, and May 2026 exhibit a highly consistent and regular periodic trend. This phenomenon is a direct consequence of the selected model architecture, feature engineering, and the inherent nature of the input data:

- The input features are restricted to `hour` (0–23) and `day_of_week` (0–6), which were transformed into a 31-dimensional binary space via **One-Hot Encoding**. Since these temporal features are inherently cyclical and the optimized MLP acts as a deterministic mathematical function, it outputs the exact same predicted value for every occurrence of the same timestamp (e.g., every Monday at 9:00 AM results in an identical prediction).

- By utilizing `data_snapshot_time` as the temporal baseline, the model successfully filtered out the minutes-level sampling noise found in the raw `update_datetime`. This allows the model to extract the "Foundational Temporal Rhythm" of Carpark PL57 with high precision ($R^2 = 0.8949$). The resulting forecast represents the **"Expected Occupancy"** or **"Typical Daily Profile"** rather than a real-time simulation of stochastic, random events.

- The transition to the `relu` activation function within this high-dimensional feature space allowed the model to learn sharp, non-linear transitions—such as the rapid increase in occupancy during morning rush hours—more effectively than a simple linear approach. The use of **Standardization** ensured

that these cyclical features remained numerically stable across the entire 2,208-hour forecasting horizon.

In summary, the generated 2,208 numbers provide a robust baseline for long-term urban planning and driver guidance, as they accurately reflect the deep-seated periodic behavior of the facility under normal operating conditions.
